### Acknowledgments

My involvement with the subject of the cost impact of production rate changes began as a team member for Air Force Systems Command's Affordable Acquisition Approach (A<sup>3</sup>) study in 1982. Subsequently, as the manager for the development of the AFSC Production Rate Model, I gained valuable experience working with the production rate issue. This thesis represents the culmination of my work and experience in this area. However, it was only with the help of numerous others that it was possible. I would like to thank a few of them here. First, I would like to thank Headquarters Air Force Systems Command, Directorate of Cost and Management Analysis (HQ AFSC/ACC) for sponsoring this thesis as part of their Cost Analysis Research program, with a special thanks to Captain Thurman Gardner. Thanks also to Mr. Gale Myers, Mr. Lou Kratz and, Ms. Michal Bohn of The Analytic Sciences Corporation (TASC).

I owe a special thanks to my advisor, Mr. Richard L. Murphy. Without his help and insight this thesis would not have been possible.

Fittingly, I would like to thank those few special people who kept me going when things were worst. First, I cannot thank enough my new wife, Charleen W. Bolton (31 August 1985), for taking over all of my last minute wedding arrangements, sacrificing our honeymoon, and sticking with me through it all. Finally, I would like to thank the Charles W. Lundy family. Without their help and caring I would still be single (and working on this thesis) today.

Hugh K. Bolton, Captain, USAF

## Abstract

The need to make decisions concerning production rate changes in today's cost conscious environment requires that accurate estimates be made of their impact on cost. The Analytic Sciences Corporation (TASC) developed a model for Air Force Systems Command (AFSC) for this purpose. This model, along with two alternative formulations of the production rate problem is the subject of this investigation.

Based on this analysis it has been determined that the current AFSC model is capable of providing more accurate estimates than the standard unit learning curve model which it is derived from. The first alternative formulation, which includes an additional variable to account for changes in production rate, was shown to consistently provide more accurate estimates than the current model. Since it is based on the current formulation, it can easily be incorporated into the present AFSC model. It is recommended that Systems Command do so. The second formulation, which is based on the unit learning curve model with the exponent expressed as a function of production rate, also provides more accurate estimates than the current formulation though, not as consistently. There is evidence which suggests that this formulation is capable of providing more accurate estimates than the first alternative for certain types of programs. It is recommended that this be further investigated.

EVALUATION OF THE AIR FORCE SYSTEMS COMMAND  
PRODUCTION RATE MODEL AND ALTERNATE FORMULATIONS

I. Introduction

The intent of this thesis is to evaluate the Air Force Systems Command Production Rate Model, provide recommendations which could improve upon the current formulation, investigate alternate formulations, and provide a basis for determining which alternative will be most useful in helping Systems Command achieve its desired objectives.

General

Program cost growth has been a constant barrier to effectively managing weapon systems acquisitions. In the past, however, it was possible that ineffective cost management could be overshadowed by technical achievement. Today this is much less likely. The public's watchful eye is keenly focused on the Pentagon, and more than ever before, all areas of defense spending are being challenged. With the major cuts social programs have received in recent budgets the public will no longer stand for "fat" in the Department of Defense.

The Department of Defense has been quick to initiate actions in response to congressional pressures to improve cost control. All three services continue to strive for the technical excellence which has become the earmark of United States Defense. Nevertheless, with their budgetary necks being threatened daily with the chopping block, an increasing emphasis is being placed on controlling all phases of weapon systems' costs.

Decision makers within the Department of Defense charged with

controlling weapon systems acquisition costs recognize that producing at more efficient production rates is one way to achieve some measure of cost stability. There is the potential to save billions of dollars and significantly reduce acquisition times as well. Professor of Engineering Management for the Defense Systems Management College, Mr. David Acker, states that "producing a defense system at an economic production rate can provide a financial savings, decrease the production time for the system, and decrease the time to complete deployment of the system" (1:7). This is recognized in a major initiative of DoD's Defense Acquisition Improvement Program which now requires that defense systems be acquired at cost efficient production rates whenever possible (1:6; 7:9).

Unfortunately, there are a number of factors which make buying at cost efficient rates impractical. For instance, Acker states that in some cases "maintaining a 'warm' production line may be more important to our defense industrial base than producing at the economic rate" (1:7). In addition to strategic considerations such as this, there are a number of budgetary and other factors which influence production rate decisions. Annual budget constraints, for example, are often major determinants of program buy schedules. Many times the choice comes down to cutting back on the current year's production quantities for certain programs or completely foregoing other badly needed projects.

Since decision makers are often required to make these trade-offs there is a strong demand in DoD for an analytical tool which can quickly and accurately measure the cost impact of program schedule changes which equate directly to increases or decreases in annual production rates. To this end, Air Force Systems Command contracted with The Analytical

Sciences Corporation (TASC), an independent research and consulting firm in Reading, MA, to develop the AFSC Production Rate Model.

#### Production Rate Effect

It is fairly well accepted within the Defense Department that varying the rate at which a manufacturer produces a product will have an impact on the per unit cost of that product. Estimates indicate that changes in F-15 production rates accounted for \$2 billion of cost growth in FY81 dollars. Stated another way, cost growth associated with program stretch-outs on the F-15 amounted to enough to purchase an additional 400 of the fighter aircraft (16; 7:7). Figure 1, which is derived from actual cost data, graphically displays the effect of production rate on per unit cost for fixed-wing type aircraft.

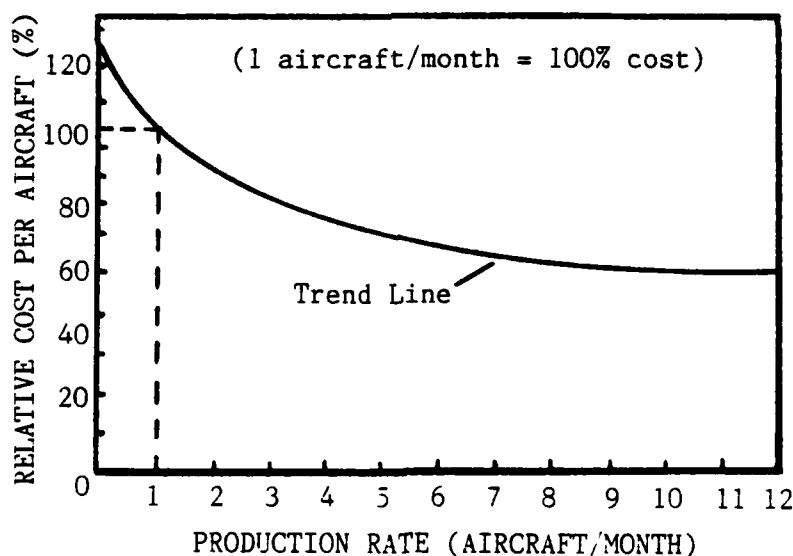

Figure 1. Sensitivity of Fixed-Wing Aircraft Cost to Production Rate (5; 7:7).

It clearly illustrates how costs can decrease (increase) as higher (lower) rates of production are utilized. The Analytic Sciences Corpo-

ration acknowledges this trend as well, but with the addition of a "minimum cost point" beyond which further increases in production rate begin to yield higher per unit costs (6:Sec 3, 9; 2:Sec 1, 4). This idea will be explored further in a later chapter. The actual shape of the curve will vary depending on a number of factors among which are the size of the total production run relative to the capacity of the production facility, the capital intensity of the production facility and, the nature of the item being manufactured. The important thing to remember here is the definite relationship which can be demonstrated between cost and production rate.

The actual impact production rate has on the per unit cost of a weapon system can theoretically be divided into three separate but interrelated effects as seen in figure 2.

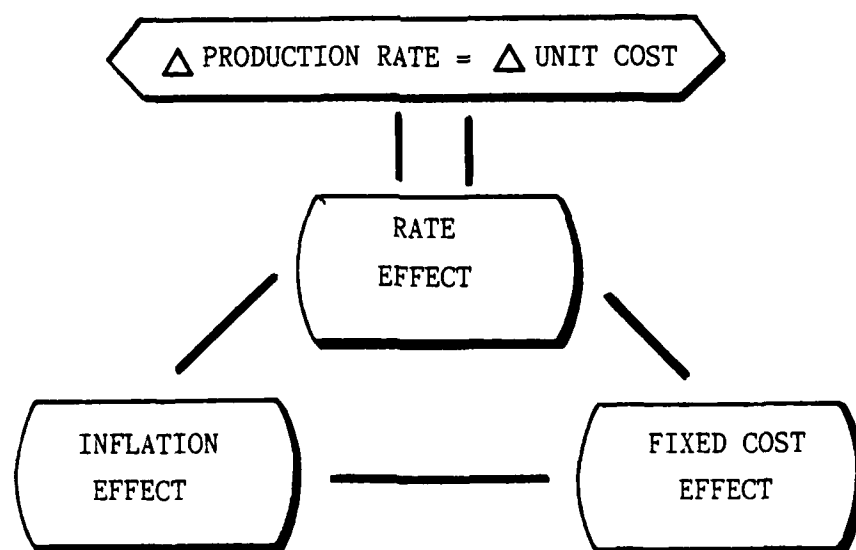

Figure 2. Three ways changes in production rate can cause changes in unit costs.

The first effect is due to instabilities introduced into the

process of learning when the assumption of constant production rate is violated. The theory of learning is discussed further in Chapter 2. In addition to this there is a pure rate effect which is evident because of changes in the utilization of capital. This forms the basis for the "bathtub" shaped cost curve which will be discussed later. Fixed cost effects are present for two reasons. First, varying production rates causes the fixed costs of the production facility to be allocated over a larger or smaller base. Additionally, since total fixed costs are a function of time, rate changes which increase or decrease the number of time periods required to complete production will impact the total fixed costs ultimately allocated to the program. Finally, the effects of inflation are encountered as schedule changes alter funding profiles. Quantities which are shifted to different years are subject to different price levels.

#### The Model

The Air Force Systems Command Production Rate Model was developed to assess the per unit cost impact of production rate variations as an aid for decision makers. It was intended to provide the basis for rough order comparisons among various production schedules under consideration for a given program. There is some evidence suggesting that when used solely for these so called "what if" type exercises, within the range of available data the current model will adequately perform this intended function.

Systems Command does not currently intend to use the Production Rate Model as an estimating tool. However, too often numbers quoted during speculative what if exercises end up being accepted as approved

estimates. This can only serve to compound the problems of controlling cost. With proper validation and statistical testing the model may eventually be accepted for estimating. However, there is some evidence to suggest that the present formulation is not logically sound and there are perhaps other forms which will be better suited to more rigorous requirements. This thesis proposes to address this issue.

### Scope and Limitations

This thesis focuses upon evaluating the Air Force Systems Command Production Rate Model as it was formulated by The Analytic Sciences Corporation. References to other efforts which aimed at quantifying the cost impact of production rate variations are made for background purposes and where necessary to support the analysis only. Exclusion of extensive discussions of these other efforts is not intended as a statement of their potential value; that is left for future research. It is intended only as a necessary exclusion to limit the scope of this current effort. Of the three production rate effects previously discussed; learning, fixed cost, and inflation, only learning is addressed in this thesis. The effects of fixed costs are neglected by considering only recurring unit costs in the analysis, and inflationary effects are eliminated by doing the analysis in constant year dollars. Additionally, the model is assessed solely as it applies to defense systems acquisitions; in particular, Air Force systems. Finally, although this thesis assumes no in-depth quantitative background on the part of the reader, a basic understanding of statistical methods is helpful. An explanation of underlying mathematical techniques and formulae is presented only where it is necessary to aid in a basic understanding of

the analysis. Where appropriate the concepts behind unusual techniques are explained and references to supplementary background material are provided. Data used in this thesis consists of cost and quantity information for 41 Air Force programs, both current and historical, in six categories: (1) bomber aircraft, (2) fighter aircraft, (3) electronics, (4) helicopters, (5) tactical armaments, and (6) tactical missiles. The data set was extracted from the AFSC Production Rate Model Data Handbook, compiled by The Analytic Sciences Corporation from official DoD sources. For a further discussion and listing of the data used in this thesis see Appendix A: Data.

### Research Objectives

This thesis centers upon several research objectives as outlined below:

- The first objective is to evaluate the current (TASC) model formulation and determine if it is capable of producing logically sound and statistically acceptable results with respect to production rate changes.
- The second research objective is to investigate two alternate formulations to the production rate problem. The first alternative incorporates a measure of production rate change as an additional variable to help explain its impact on unit costs. The second alternative formulation looks at a different model specification which allows the data to determine the optimal rate of production, something the TASC model will not do.
- The final objective is to compare the results obtained in meeting the first two objectives and to provide justification for selecting one approach to best address the production rate issue.

### Summary

Decision makers in the Department of Defense are faced with an increased need to make timely and accurate decisions on matters which

affect weapon system costs. It is accepted that program schedule perturbations with the associated fluctuations in production rates will impact the per unit cost of a system. In order to make intelligent trade-offs between producing at cost efficient production rates and outside budgetary and political considerations they require a tool which can assess the cost impact of production rate changes. A model currently exists within Air Force Systems Command which purports to be able to do this. However, the current formulation of this model may not consistently provide logical and acceptable estimates. There may be alternate formulations which could do better. This is the subject of this investigation.

## II. Background

Review of the pertinent literature reveals that previous research in the area of production rate changes centers almost exclusively on the theory of learning curves. The current Air Force Systems Command Production Rate Model is itself based upon this concept. The actual formulation The Analytic Sciences Corporation uses in the AFSC model has been investigated by a number of other researchers. The critical difference between these other efforts and the TASC model is not in the formulation itself but in the approach used to fit the curve to the data.

This chapter provides a brief discussion of the theory of learning curves as it applies to the production rate problem, and then focuses on some of the various works which have contributed to the evolution of the TASC formulation. Chapter three then discusses TASC's formulation of the production rate model and provides a brief description of the TASC curve fitting approach.

### The Learning Curve

The theory of learning is one of the most widely accepted ideas in the field of cost analysis. First proposed in 1936 by T. P. Wright, the learning curve is based on the premise that the resource requirements for a specified task decrease with consecutive repetitions of the task (19:122-128). Two basic formulations of this theory have emerged over time as standards in the aerospace industry. The unit curve formulation indicates that as the cumulative quantity of an item being produced increases by a fixed percentage, the cost (normally expressed in labor hours) of an individual production unit decreases by some fixed percentage. The cumulative average learning curve formulation on the other

hand assumes that as the cumulative quantity of production increases by a fixed percentage the cumulative average production cost decreases by some fixed percentage. For general purposes the differences between the two formulations are minimal. To aid in the analysis this paper will focus exclusively on the unit curve formulation, which is the formulation used by TASC in developing the AFSC model. The usual presentation of this formulation is provided in equation 1 below:

$$Z = AX^b \quad (1)$$

where

$Z$  = cost of unit  $X$   
 $A$  = cost of the first unit produced (constant)  
 $X$  = cumulative quantity  
 $b$  = learning curve parameter

In typical applications it has become accepted to express this formulation in terms of a doubling of quantity. The learning curve parameter,  $b$ , therefore becomes:

$$b = \ln s / \ln 2 \quad (2)$$

where

$s$  = slope of the learning curve

For example, a unit curve having a learning curve parameter of  $-0.321928$  has a slope of  $s = 2^b = 0.80$ . This means that unit 2 will cost 80 percent as much as unit 1, that unit 4 will cost 80 percent as much as unit 2, and so forth.

Figure 3 is an example of a typical learning curve. Plotted on an arithmetic scale it is easy to see that normal linear least squares regression would be inappropriate for solving for the parameters  $A$  and  $b$

in equation 1.

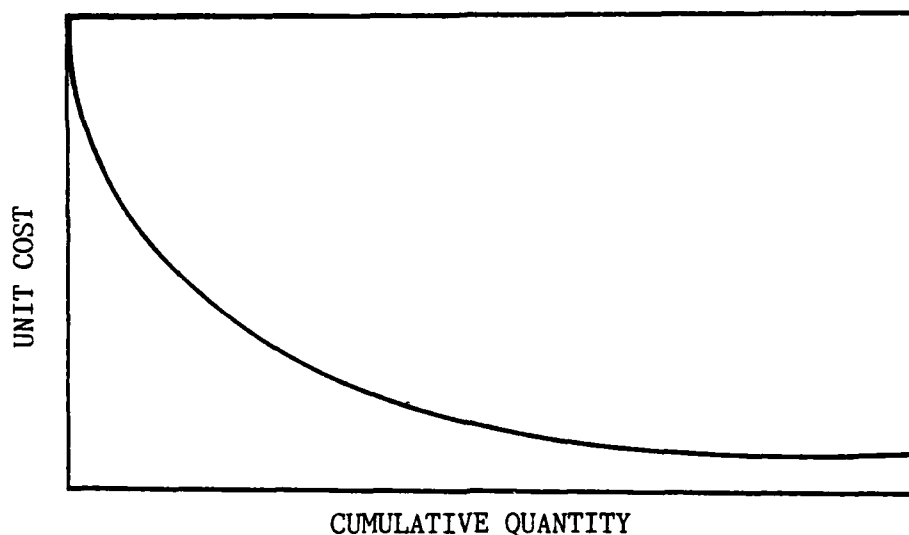

Figure 3. The Learning Curve.

In practice, equation 1 is transformed using a log-linear transformation and normal linear least squares regression is then used to solve for A and b. Equation 3 shows this transformed equation which plots as a straight line on a log-log scale:

$$\ln Z = \ln A + b \ln X \quad (3)$$

Assumptions of this formulation of the cost improvement (learning) curve include among other things, consecutive production, constant production process, constant workforce, and, in general, constant production rate. Since violating any of these assumptions could introduce significant errors into the relationship, and subsequent cost estimates, researchers have attempted to account for such violations. This paper focuses on violations of the constant production rate assumption.

#### Cost Impact of Production Rate Changes

Review of the pertinent literature indicates that there have been

numerous formulations proposed for assessing the cost impact of production rate changes. As previously noted, the majority of these involve the learning curve concept.

Commander Steve Balut, USN, while a cost analyst with the Office of the Secretary of Defense (Program Analysis and Evaluation), proposed a model which provides an adjustment factor for rate based on those program costs which are not considered fixed in the short term. The model uses a two-step process to adjust for rate changes. The first step involves the normal application of the learning curve for quantity changes. The second step suggests a heuristic approach based on equation 4 below to adjust for rate changes (3:63-76):

$$F_i = PR(Q_i^{\text{old}}/Q_i^{\text{new}})^a + (1 - PR) \quad (4)$$

where

$F_i$  = adjustment factor for lot i (from step one)

$Q_i^{\text{old}}$  = old quantity in lot i

$Q_i^{\text{new}}$  = new quantity in lot i

P = fraction of price represented by overhead

R = fraction of overhead fixed in the short term

a = rate adjustment slope

Source: (3:66-70).

The factor,  $F_i$ , is applied by multiplying the estimates developed in step-one to come up with a new, rate adjusted estimate.

There are a number of limitations to this approach. First, the model is only useful within a small range. Commander Balut himself states that "the model should be applied with caution, and then only within the range of data supporting its development..." (3:75). Second,

the model requires the input of contractor data which is difficult to find and often inconsistent among various contractors. Finally, the model reported in Balut's paper was developed using a non-linear curve fitting approach with only 11 data points. Balut suggests that additional data points could help improve its confidence (3:76).

Another approach was proposed by Dr. Charles Smith, an operation research analyst for the Army Procurement Research Office (13:77-83). Smith's model is also based on the learning curve concept and redistribution of overhead costs. He suggests however, that "the model is based on the premise that costs dependent on time rather than cumulative quantity are the major explainers of the cost impact of rate changes" (13:80). This model is sensitive to changes in variable costs associated with quantity changes via the same mechanism as Balut's model, the learning curve. Smith's model however, then multiplies annual fixed production costs by the number of years the program is in production and adds this to the variable costs. If the program is stretched-out while holding the total quantity constant (thus reducing production rate) then the total amount of fixed costs charged to each production unit will increase accordingly or vice versa. Smith's model is presented in equation 5 below:

$$Y = \frac{\sum_{X=1}^Q AX^b + T(FC)}{Q} \quad (5)$$

where

Y = cumulative average cost of production  
 Q = total quantity produced  
 A = cost of the first unit produced (constant)  
 X = cumulative quantity

b = learning curve parameter  
T = number of years of production  
FC = annual fixed costs for production

Source: (13:81)

The appeal of this approach is its simplicity. Unfortunately, it is limited in that it fails to provide better than a rough order estimate of the effect of rate changes. One reason for this failing is the fact that many costs (for example, depreciation) are only fixed in the short term. Smith feels that the model can be modified to overcome this limitation but recognizes that this would involve the difficult task of estimating the annual fluctuations in fixed costs (13:81).

The final production rate formulation discussed in this chapter is one which has been investigated by a number of different researchers including Dr. Larry L. Smith and John C. Bemis (4:84-94; 14; 1:9; 2: Sec 1, 6-7; 6: Sec 3, 13; 9:3; 12:6-7; 5; 8:259). Instead of providing an adjustment for the reallocation of fixed overhead costs, it incorporates a parameter for production rate directly into the learning curve model. (Note that this formulation ignores the effects of inflation and fixed costs because in typical applications parameters are estimated using only recurring costs in constant year dollars.) This formulation is presented below:

$$Z = AX^bY^c \quad (6)$$

where

Z = cost of unit X  
A = cost of the first unit (constant)  
X = cumulative quantity  
b = learning curve parameter  
Y = production rate  
c = production rate parameter

A graphic representation of equation 6 is given in figure 4.

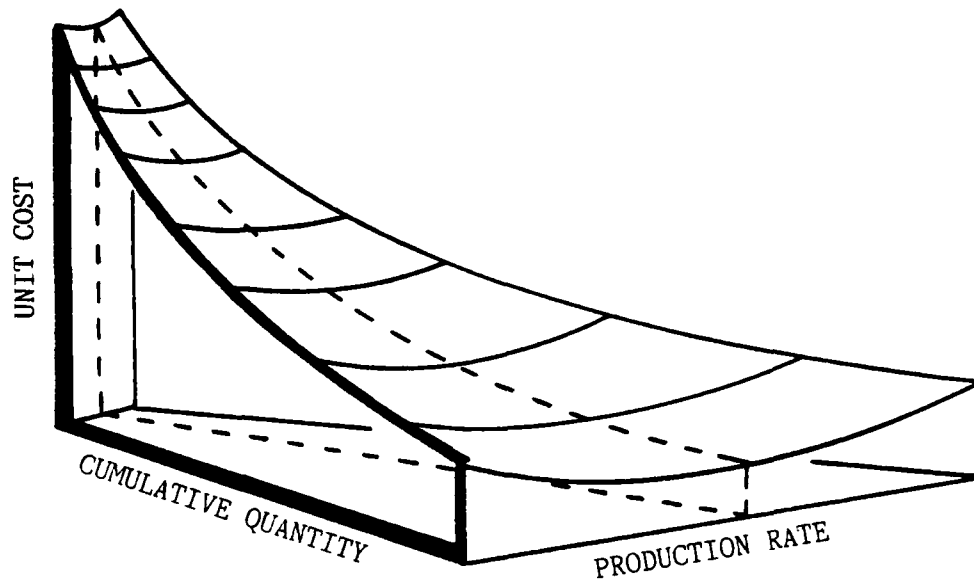

Figure 4. Graphic Representation of the  $Z = AX^bY^c$  Production Rate Formulation (1:9; 2: Sec 1, 6; 4:86; 6: Sec 3, 12; 9:3; 8:259).

The darkened lines in the figure represent the basic learning curve model,  $Z = AX^b$ . The remainder of the figure represents the incorporation of the production rate parameter.

The appeal of this formulation is two-fold. First, once the parameters have been estimated, it requires very little information to use the model. The only thing it requires which the standard learning curve formulation does not is a production rate and it is convenient to use readily available annual buy schedules as a proxy for this. Second, it builds directly upon an already well established model, the learning curve. Extensive use of the learning curve model throughout the Department of Defense can help provide a general acceptance of this production rate formulation both within the cost analysis community and within the decision making bodies which approve their estimates. Additionally, using log-linear transformations the model's parameters,  $A$ ,  $b$ , and  $c$ ,

can be estimated using linear least squares regression just as is done for the simple learning curve formulation. The linearized equation is presented below:

$$\ln Z = \ln A + b \ln X + c \ln Y \quad (7)$$

Unfortunately, there are several problems associated with using a linear approach to solve this formulation. First, there is a problem of collinearity between the model's predictor variables, X and Y. Several researchers, including Bemis and TASC, have identified this limitation of the data (4:93; 6: Sec 4, 2-4). The presence of this condition basically means that each variable is explaining part of the variation in the data associated with the other thus making it impossible to separate the effects of quantity changes (learning) from the effects of production rate changes.

The next major limitation of the linear approach used by Bemis and others is that error associated with using estimated lot plot points is introduced into the model. Since cost data for most major programs is readily available only by production lot and not by individual unit, it is necessary to enter data in the form of average unit cost per lot and to estimate a lot plot point as a coordinate value. Inasmuch as the actual unit costs within a lot are not uniform (That is, they decrease at a decreasing rate because of learning.) the true lot plot point will not lie in the center of a given lot.

For example, suppose that a lot of 10 units has a total lot cost of \$1,000. Various scenarios could apply. If the lot is completely uniform then each unit will cost exactly \$100 and the lot plot point would be 5. Now, suppose that the cost of unit 1 is some value greater than \$100 and

that the value of successive units decreased at a constant rate such that the sum of the ten units was still \$1,000. In this case the average unit cost of the ten units would be \$100 and the plot point would still be 5. Finally, suppose that the cost of unit 1 were some value and that the values of successive units decreased logarithmically (as with the learning curve) such that the total lot cost was again \$1,000. In this final case the average unit cost for the ten units is still \$100 but, the lot plot point would lie somewhere to the left of 5. The position of the true lot plot point is a function of the slope of the learning curve. The steeper (flatter) the slope, the farther left (right) the point will lie.

In general, rules of thumb are used to provide estimated lot plot points for evaluating learning curves. The error associated with these plot point estimates consequently introduces bias when solving for the parameters in equation 6.

Finally, several researchers, including Sherbrooke and Associates, in a critique of various acquisition models, have suggested that a direct non-linear method will provide a better fit of the data while perhaps avoiding some of the statistical problems inherent in the linear approach (12:50).

The approach used by TASC in developing the AFSC Production Rate Model is direct non-linear. Chapter three discusses their method in detail.

### III. The TASC Approach

The AFSC Production Rate Model is based upon the the formula introduced in chapter two, equation 6. The key difference between previous efforts and TASC's work is that TASC uses a direct non-linear method for solving for the parameters, A, b, and c. For convenience, equation 6 is presented again below:

$$Z = AX^bY^c \quad (6)$$

where

- Z = cost of unit X
- A = cost of the first unit (constant)
- X = cumulative quantity
- b = learning curve parameter
- Y = production rate
- c = production rate parameter

TASC assumes that the response curve of cost to production rate is "bathtub" shaped as shown by the long-run cost curve in figure 5 below:

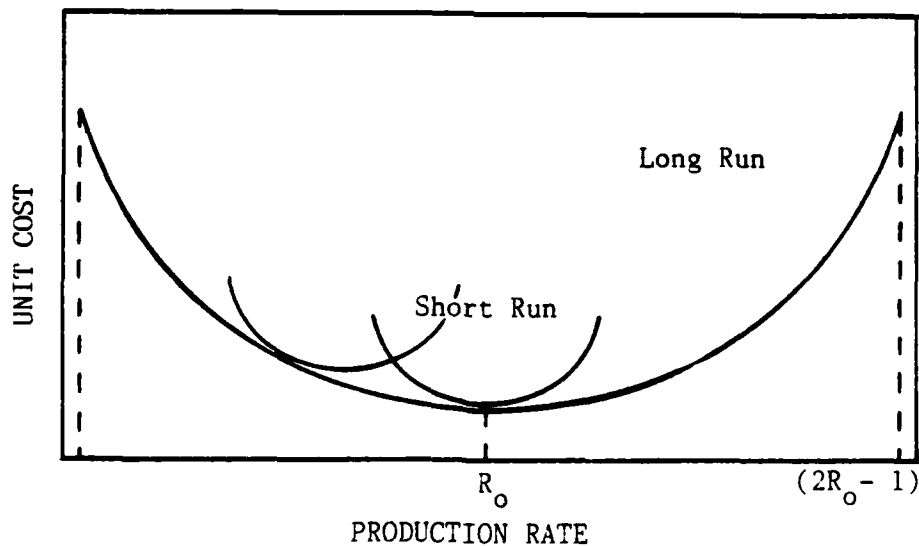

Figure 5. TASC's "Bathtub" shaped average cost curve (6: Sec 3, 9).

The long run cost curve assumes all inputs can vary. Its shape reflects the inefficiencies associated with very small or very large operations. The short run cost curve assumes that plant and equipment are fixed. Its shape reflects the inefficiencies associated with under or over utilization of capital. Both curves have a minimum ( $R_0$ ), and both are relatively flat in the center, so that small changes in rate around  $R_0$  have little effect on cost. However, the  $R_0$  for a specific short run cost curve may differ from the  $R_0$  for the the long run curve.

TASC assumes that the curve is symmetric about  $R_0$ . This assumption implies that a percentage increase in production rate above  $R_0$  will yield the same per unit cost impact as a like percentage decrease in production rate below  $R_0$ . Since the formulation given in equation 6 cannot account for this, the variable Y (production rate), is expressed as shown below:

$$Y = \begin{cases} R & \text{if } R \leq R_0 \\ 2R_0 - R & \text{if } R_0 < R \leq 2R_0 - 1 \end{cases} \quad (8)$$

where

Y = production rate  
R = production rate for a given lot  
 $R_0$  = minimum cost production rate

Source: (6: Sec 3, 13)

This function transforms production rates greater than  $R_0$  into equivalent rates between 1 and  $R_0$ . The constraint,  $R \leq 2R_0 - 1$ , recognizes that rates greater than  $2R_0$  would give Y values of less than 1.

#### Fitting The Curve

To solve equation 6 for A, b, and c TASC first estimates the total

cost for each lot by integrating over the total number of units for each lot as shown in equation 9 at the top of the next page.

$$TC_i' = \int_{Xl_i}^{Xu_i} AX^b Y_i^c dX = [A/(b+1)][Xu_i^{(b+1)} - Xl_i^{(b+1)}][Y_i^c] \quad (9)$$

where

$TC_i'$  = estimated total cost of lot i

$Y_i$  = production rate for lot i

$Xl_i$  = cumulative quantity through lot i-1

$Xu_i$  = cumulative quantity through lot i

A = constant

b = learning curve parameter

c = production rate parameter

Source: (6: Sec 4, 6).

Actual total lot costs are then found by multiplying actual lot quantity (known) by the average unit cost for the lot (known). Actual total lot cost for each lot, i, is denoted  $TC_i$ .

Finally, the unknown parameters A, b, and c are solved for by minimizing the sum of squared errors between  $TC_i$  and  $TC_i'$  as shown in equation 10 below:

$$\sum_{i=1}^N w_i [TC_i - TC_i']^2 \quad (10)$$

where

N = total number of lots

$w_i$  = weight of lot i (where  $\sum w_i = 1$ )

The weights,  $w_i$  are determined by the user and reflect the relative importance of each lot (6: Sec 4, 6). Normal learning curve estimation assigns equal weights to all lots. Some models on the other hand weight each lot based upon the size of the lot relative to the total quantity as shown below:

$$w_i = [\text{quantity in lot } i] / [\text{total quantity}]$$

The method used by TASC allows the model user to specify the weighting scheme to be used for each program. It is assumed that TASC uses equal weighting for all lots in their work for Systems Command. However, this was not reflected in the available documentation and therefore cannot be stated with certainty.

The technique actually used by TASC to minimize equation 10 is Newton's Method and involves an iterative solution to the matrix of non-linear equations gained through partial differentiation of equation 10 with respect to parameters A, b, and c. Because of the complexity of Newton's Method a discussion of it is not included in this section of the thesis. For a further discussion of the technique refer to Appendix B: Newton's Method.

#### IV. Methodology

This chapter outlines the methodology used to meet the research objectives which were first discussed in chapter one. For convenience each objective will be repeated at the beginning of its corresponding section in this chapter.

##### Evaluating The TASC Model

- The first objective is to evaluate the current (TASC) model formulation and determine if it is capable of producing logically sound and statistically acceptable results with respect to production rate changes.

SAS/TRAC Comparisons. When TASC developed The Air Force Systems Command Production Rate Model they did not provide their proprietary curve fitting program, TRAC (TASC Rate Analysis Curve). Instead, they provided a program written for the Statistical Analysis System (SAS) which could be used by Systems Command to replicate TASC's results and for fitting the curve to future programs. For a listing of the SAS program and description of the program steps see Appendix C: SAS Programs.

The first step before analyzing the Systems Command model is to determine if the SAS program is indeed capable of replicating TASC's work. To accomplish this, parameters will be estimated for each of the 41 data sets using the SAS program and the results will be compared to those estimated using TRAC. Because of the proprietary nature of the TRAC curve fitting routine it is likely that the SAS program will not provide an exact replication of the parameters TASC predicted. Therefore, if each of the three parameters predicted by SAS for a program are

within ten percent of the corresponding parameters predicted by TASC this will be considered adequate replication for that particular program. If at least 75 percent (thirty) of the 41 programs meet this criteria it will be concluded that the SAS program adequately replicates TASC's results. The following simple equations will be used for the comparison:

For a given program,

$$\text{if } |(A_{\text{TRAC}} - A_{\text{SAS}})/A_{\text{TRAC}}| \leq 0.1$$

and

$$\text{if } |(b_{\text{TRAC}} - b_{\text{SAS}})/b_{\text{TRAC}}| \leq 0.1$$

and

$$\text{if } |(c_{\text{TRAC}} - c_{\text{SAS}})/c_{\text{TRAC}}| \leq 0.1$$

then: Conclude that SAS = TRAC for that particular program.

Residuals: Learning vs. Production Rate Models. The next step in evaluating the TASC formulation is to determine if the model is providing a more accurate estimate of cost than the standard learning curve model is capable of providing. The basic premise behind including the rate parameter in TASC's model is that the learning curve model is misspecified and that the inclusion of rate as an independent variable accounts for a significant proportion of the variation in the data. To test this premise, costs are estimated using a standard learning curve model and the residuals are compared to to the model which includes the production rate variable. Residuals are the differences between the actual values and the values predicted by the model.

Step 1. Calculate the sum of the squared residuals for each of the 41 programs for each formulation. Squaring accounts for the fact that

the residuals can be either positive or negative and would otherwise cancel each other out.

Step 2. If the value for the TASC formulation is less than the value for the standard learning curve model by 10 percent or more then conclude that the production rate formulation explains a significant portion of the variation in the data that is not explained by the standard learning curve model. If the value for the production rate formulation is greater than the learning model for a particular program this indicates that the addition of the rate variable actually made the estimate worse for some reason.

This test is done on a program by program basis. It is expected that programs with stable rates of production will show results similar to those achieved with the normal learning curve model. This is because as the parameter  $c$  approaches the value of zero (as it would with stable production rates) the production rate term goes to unity and the model reverts back to the standard learning curve formulation. On the other hand, programs with the largest shifts in rate should show a significant improvement by including the production rate term.

The learning curve model which is used in this analysis is ICLOT and was chosen for several reasons. First, it was readily available and is widely used and accepted in the cost analysis community. Second, it uses an iterative process to determine lot plot points similar to what is done in the TASC approach through Newton's method. This minimizes the amount of error which could be contributed to lot plot point bias. Finally, it uses the same unit curve formulation which is the basis for TASC's model.

Logic Analysis. In this final step TASC's formulation is analyzed to determine if it is logically sound. In accomplishing this, assumptions TASC makes with respect to the production rate model and assumptions of the non-linear curve fitting approach are evaluated for

validity and impact. For instance, the non-linear curve fitting technique requires that the production rate be held constant for each lot. Since annual buy schedules are being used as a proxy for production rate is this a valid assumption, and if not, to what extent does violation of this assumption invalidate the model? The key to this section is in insuring that the model is not merely providing a good fit of the data, but is logically capable of providing acceptable estimates within the range of production rate data. It is characteristic of learning curves that cost estimates are always for quantities which lie beyond the range of historical data. However, learning curves have progressed to the stage where the theory underlying the phenomena has been well defined, empirically tested, and found to be sound. Confidence in this theory allows projection beyond the range of the data with reasonable confidence in the outcome. Since the impact of production rate on unit costs is yet to be adequately defined and empirically verified, care needs to be taken when applying any production rate model. This area offers great opportunities for future research.

#### Evaluating Alternate Formulations

- The Second research objective is to investigate two alternate formulations to the production rate problem. The first alternative incorporates a measure of production rate change as an additional variable to help explain its impact on unit costs. The second alternative formulation looks at a different model specification which allows the data to determine the optimal rate of production, something the TASC model will not do.

Logic Analysis. The first step in evaluating the two alternate formulations will be to analyze the logic behind their selection. Both

models are based on the unit learning curve formulation just as the TASC formulation is.

The idea behind alternative one is that the change in production rate from one lot to the next is as important in explaining the impact of production rate on cost as is the rate itself. Moving from a higher rate of production to a lower rate, or from a low rate to a higher rate, would have an impact on the efficiency of the production process which would not be captured by looking at production rate alone. To account for this a new variable, R, was added to the TASC formulation. R is defined as the ratio of the production rate in the current lot to the rate in the previous lot. The formulation of alternative one is shown below:

$$Z = AX^bY^cR^d \quad (11)$$

where

- Z = cost of unit X
- A = constant
- X = cumulative quantity
- b = learning curve parameter
- Y = production rate
- c = production rate parameter
- R = ratio of the rate in lot i to the rate in lot i-1
- d = production rate change parameter

The second alternative is formulated to model the bathtub shaped production rate curve mathematically. To do this it uses the standard unit curve model with the exponent expressed as a function of Y, production rate. A quadratic function was selected since it best models the expected shape of the production rate curve with a minimal number of additional parameters. Alternative two is shown at the top of the following page.

$$Z = AX^{(b+cY+dY^2)} \quad (12)$$

where

$Z$  = cost of unit  $X$   
 $X$  = cumulative quantity  
 $Y$  = production rate  
 $A, b, c, d$  = model parameters

So long as  $c < 0$  and  $d > 0$ , this formulation will produce an optimum production rate,  $R_0$ , at which unit costs will decline along the steepest possible learning curve slope. If the production rate deviates from  $R_0$  in either direction, the slope of the learning curve becomes less steep, which means a slower rate of learning. This formulation is consistent with the expected response pictured in figure 4.

Asymptotic Confidence Intervals. In addition to its other output the SAS NLIN procedure provides a 95% confidence interval estimates for the coefficients. If an interval estimate for a particular coefficient bounds zero then the hypothesis is accepted that the true parameter is equal to zero and not significant at the 95% confidence level. These confidence intervals will be analyzed to determine if the parameters included in the two alternate formulations are significant. However, it is probably unreasonable to demand that this hypothesis be tested at such a high level of confidence. It increases the probability of accepting the hypothesis when it is false. Therefore, coefficients which fail the 95% test of significance will be reevaluated at the 80% level if it appears that lowering the level of confidence could change the outcome of the test. A 95% confidence interval estimate that appears to be nearly symmetrical around zero would undoubtedly still include zero even if the level of confidence were reduced to 80%.

### Comparing Approaches

- The final objective is to compare the results obtained in meeting the first two objectives and to provide justification for selecting one approach to best address the production rate issue.

Residuals. This step is a repeat of the analysis performed in comparing the TASC model to the standard learning curve model. The sum of squared residuals for the TASC model and the two alternatives will be compared on a program by program basis. The goal is to identify the model which consistently provides the more accurate estimate over a wide range of programs.

Based upon this evaluation and the discussion in the previous two sections, the three alternatives (the TASC model and two proposed alternatives) will be compared. If one alternative is an obvious standout, that is, consistently provides improvements in the sum of squared residuals over the other two formulations, then the results of the analysis will be conclusive in favor of that formulation. If, however, the evaluation indicates that two formulations are equally capable of providing consistent improvements then the results will be conclusive in favor of that model which is more logically supportable. Finally, if none of the three formulations is capable of providing logically sound and statistically acceptable results it will be concluded that Systems Command should continue using their present model until a better one can be developed.

## V. Analysis

This chapter presents the results of the analysis which was performed on the current Air Force Systems Command Production Rate Model as developed by The Analytic Sciences Corporation (TASC) and the two proposed alternatives.

### The TASC Model

This section discusses the current production rate model. The formulation of this model, which was discussed in chapter three, is found in equation 9. It is repeated below for reference:

$$TC_i' = \int_{Xl_i}^{Xu_i} AX^b Y_i^c dX = [a/(b+1)][Xu_i^{(b+1)} - Xl_i^{(b+1)}][Y_i^c] \quad (9)$$

where

$TC_i'$  = estimated total cost of lot i

$Y_i$  = production rate for lot i (constant for a given lot)

$Xl_i$  = cumulative quantity through lot i-1

$Xu_i$  = cumulative quantity through lot i

A = constant

b = learning curve parameter

c = production rate parameter

Source: (6: Sec 4, 6).

SAS/TRAC Comparisons. The parameters A, b, and c which were estimated by TASC's proprietary curve fitting program (TRAC) can be found in Appendix D, section 3. Those estimated using the SAS routine

which TASC provided to Systems Command are in section 2. The following are the results of the test discussed in the previous chapter:

- Eighteen of the forty-one programs met the ten percent criteria for all three parameters.
- Thirteen programs had one parameter which was beyond the criteria while the other two remained within. All but one of these failed on parameter A.
- Six programs met the criteria on only one parameter. Of these, five met on parameter b and one on c.
- Four programs failed to meet the ten percent criteria on any parameter.

Since less than thirty programs met the criteria for all three parameters it should be concluded that the SAS program provided by TASC does not adequately replicate the parameters estimated using TRAC. There are, however, several considerations which suggest that these results are not reliable. First, the parameters b and c were not compared directly. Instead, the slopes corresponding to the two parameters were compared. (Recall from chapter two that the slope corresponding to the parameter b is  $2^b$ , and likewise for c.) This was done because TASC presented only the slopes corresponding to the parameter values and not the parameters themselves in their report. Furthermore, they reported the slopes only to an accuracy of two decimal places. Because of rounding, the actual value of the parameter can take on a wide range of values. For example, any value from 0.945 through 0.954 will be rounded to a slope of 0.95. The problem presents itself because of the logarithmic relationship between the slope and actual parameter (parameter =  $\ln \text{slope} / \ln 2$ ). While the difference between 0.945 and 0.954 is only 1%, the corresponding parameter values of -0.0816138 and -0.0679388

yield a difference of 16.8%.

The next problem is that small differences in the estimates of  $b$  and  $c$  cause large differences in  $A$ . This was suspected because of the twelve programs which failed to meet the criteria due to parameter  $A$ . For example, suppose that one program fitted the model to a set of data with the result that both parameters corresponded to a slope of 0.95. Given that the first 100 units cost \$1000, solving equation 9 for  $A$  produces a value of 18.477997. If another program fitted that same model to the same set of data with the result that  $b$  corresponded to a slope of 0.95, but  $c$  corresponded to a slope of 0.93,  $A$  would increase to 21.283764. An increase of only 2.1% in the slope associated with the production rate produced a 15.2% difference in the value of  $A$ . If the twelve programs which failed to meet the criteria for parameter  $A$  but satisfied the criteria for parameters  $b$  and  $c$  are considered acceptable, successful replication of SAS by TASC was accomplished for thirty-one of the forty-one programs evaluated (75.6%).

Finally, the output reported by TASC raises some unresolved issues which impact on the ability of SAS to replicate TRAC. For example, the B-58 was one of four programs which failed to meet the ten percent criteria on any of the three parameters. TASC failed to report estimated cost for lots 1, 9, and 10 of this program, even though it is a simple procedure to calculate lot estimates by solving equation 9 once parameters  $A$ ,  $b$ , and  $c$  have been estimated. Note that a total of twenty-one programs have one or more lots for which costs were not reported by TASC. The absence of reported estimates for these lots combined with the failure of SAS to replicate TRAC suggests that TASC may have modified the data set before estimating the model parameters.

If this is the case, lack of documentation makes it impossible to determine exactly what data set should be used to evaluate the ability of the SAS program to replicate the reported results.

Because of the problems identified above it was not possible to determine with certainty if SAS is capable in every instance of replicating TRAC. However, TASC recommends using SAS to estimate the parameters of their model. Furthermore, TASC states that the SAS procedure and TRAC are "equivalent" and that TRAC was validated using SAS (17: 30, 34). Therefore, given the above analysis and the assurances offered by TASC, the assumption will be made that, given the same data set, the results generated by SAS can be accepted as a reasonable replication of TRAC's output.

Residuals: Learning vs. Production Rate Models. This section discusses the results of the comparison of the TASC production rate model with the standard learning curve formulation. Since TASC's model simply adds a variable for production rate to the unit learning curve equation it should be determined if this variable improves the estimating ability of the model. The results of the ICLOT learning curve runs can be found in Appendix D, section 1. Results of the SAS runs for the TASC formulation are in section 2. Results for the two formulations were compared by calculating the percentage difference in their sum of squared residuals (SSR) for each program as shown below:

$$[(SSR_{ICLOT} - SSR_{TASC})/SSR_{ICLOT}] \times 100$$

where

$SSR_{ICLOT}$  = sum of squared residuals from the ICLOT model

$SSR_{TASC}$  = sum of squared residuals from the TASC formulation (SAS)

The results of this test are given in table I below and summarized at the top of the following page.

TABLE I  
ICLOT versus TASC Residual Comparison Summary

Program	SSR (ICLOT)	SSR (TASC)	Difference (%)
B-1B	28429	12451	56.2
B-52	8515485	2448210	71.2
B-58	705710	483386	31.5

AMRAAM	1938	1658	14.4
HARM	2435	399	83.6
MAVERICK	8259	3385	59.0
AIM-7F(R)	424	250	41.0
AIM-7F(GD)	173	84.8	50.9

- Thirty-five of the forty-one programs showed a ten percent or greater improvement in residual sum of squares over the standard learning curve model. One showed only slight improvement and five showed an increase in SSR over the ICLOT estimates.
- The average percentage improvement over the learning model for all programs was 32.3% with a standard deviation of 58.8.
- The average percentage improvement for only those 36 programs which showed an improvement was 46.4% with a standard deviation of 26.7.

Based on this evidence it is concluded that the TASC production rate formulation provides a significant improvement over the standard learning curve model. There was some evidence indicating that those programs with stable production rates improved less than those with large shifts in rate. Several programs such as the CH-46 and CH-47 helicopters, had large shifts in rate for one or two periods within otherwise stable production runs. These two programs showed 86.1% and 63.6% decreases in the sum of squared residuals respectively. Conversely, the F-100 had a small lot 1 rate but was stable throughout the remainder of the program (lot sizes for lots 2 through 5 ranged from 545 to 593), and the improvement for this program was only 3.5%. The LLLGB program made a steady build-up and then leveled off at a rate of 15600 units per year for three years. This program actually showed an increase in the residual sum of squares by going to the production rate formulation.

Logic Analysis There are several assumptions TASC makes in developing and analyzing the Systems Command model. Only those which could have a questionable impact on the validity of the model or TASC's results are considered here.

First, application of Newton's Method to the TASC formulation

requires that the production rate ( $Y_i$ ) be held constant for a given lot  $i$ . This is probably a valid assumption if the time periods for each lot are sufficiently small. While it is unlikely that production rates would differ significantly from month to month, it is highly probable that a contractor might implement a substantial change in the rate of production over a period of a year. Consequently, the use of annual buy schedules as a proxy for the production rate could introduce some error into the model. However, because of the difficulty of obtaining accurate cost/quantity data on a monthly basis, it is difficult to assess how much error is being introduced. Furthermore, the decision makers who use the model for "what if" exercises may only know the projected annual buy quantities. It does no good to build a model which requires inputs which cannot be reasonably estimated at the time the model is to be used.

The next assumption TASC makes is that the relationship between cost and the production rate is a symmetrical U-shaped curve, frequently referred to as a bathtub curve. The curve implies that an optimal rate of production exists at which unit production costs will be minimized. The assumption itself is probably reasonable. However, the model formulation used by TASC cannot generate the assumed curve. Instead, TASC has provided an algorithm which capitalizes on the hypothesized symmetry of the curve to adjust for those observations for which the rate of production is greater than the optimum (equation 8, chapter 3). The problem is that the optimal rate of production must be determined prior to the fitting of the model. If observations fall on both sides of the optimal production rate, failure to adequately adjust the data will result in distorted parameter estimates.

Next, one of the arguments TASC offers for using the non-linear approach to estimate parameters over the least squares best fit log-linear approach used by previous researchers deals with a "pseudo- $R^2$ ". TASC defines the pseudo- $R^2$  "as the squared correlation between the observed and predicted values of the independent variables" (18: Appendix B, 5). In an analysis of the F-15A/B and HARM programs TASC states that "since the value of the pseudo  $R^2$  for the non-linear model is higher than the  $R^2$  for the linear model, the non-linear model provides a better 'fit' of the data" (18: Appendix B, 5). While the  $R^2$  value for the linear model can provide a suitable measure of "fit," the pseudo- $R^2$  cannot. It can be shown that this proposed statistical measure can take on any number of values which in no way indicate the fit of the data. For example, suppose the non-linear model had provided the estimates below for two programs, A and B:

Program A				Program B		
Lot	Actual	Predicted	Percent Difference	Actual	Predicted	Percent Difference
1	54.0	53.6	0.7	56.5	67.9	-20.2
2	54.0	52.3	3.1	50.1	40.8	18.6
3	52.0	53.0	-1.9	43.7	35.0	19.9
4	50.2	53.9	-7.4	38.1	45.7	-19.9
5	48.9	48.5	0.8	32.0	25.6	-20.0

Looking at the percentage differences between the actual and predicted values above it is obvious that the model provided a better fit of program A than of B. However, pseudo- $R^2$  values for both programs would indicate otherwise. The value for program A is 0.5756 while the value for program B is 0.8086. This is just a mild example of the problems with pseudo- $R^2$ . For this reason the pseudo- $R^2$  is an invalid measure of fit and should not be used for future analyses.

Finally, TASC discusses asymptotic confidence intervals which are provided by SAS for each parameter. TASC correctly argues that if an interval for a particular parameter does not bound zero then the hypothesis that the parameter is equal to zero (i.e. has no effect) can be rejected at the 95 percent level of confidence. TASC shows that for the HARM program all three parameters are significant at this level. However, according to the SAS results listed in Appendix D, section 2, HARM is one of only four programs which showed all three parameters to be significant at the 95 percent level. Sixteen programs showed only two parameters to be significant at this level, four showed only one, and seventeen programs indicated that none of the parameters were significant at the 95 percent level. TASC does not discuss the results mentioned above. As a check, confidence intervals at the 80% level were calculated to determine if this would increase the number of programs which showed all three parameters statistically significant. Even at this lower confidence level only nine programs met the criteria.

#### Alternate Formulations

Two alternate formulations were developed to address the production rate issue. Both of these models were compared to the TASC model just discussed. The results for each of these comparisons is presented in the following sections.

Alternative one Alternative one was introduced in the previous chapter in equation 11. Integrating equation 11 with respect to  $X$  provides an estimate of total lot costs. Using the SAS NLIN procedure, parameters  $A$ ,  $b$ ,  $c$ , and  $d$  are estimated which minimize the residual sum of squares between actual total lot costs and those predicted by the

model. The result of the integration is presented below:

$$TC_i' = \int_{Xl_i}^{Xu_i} AX^b Y_i^c R_i^d dX = [A/(b+1)] [Xu_i^{(b+1)} - Xl_i^{(b+1)}] [Y_i^c R_i^d] \quad (13)$$

where

$TC_i'$  = estimated cost of lot i

$Y_i$  = production rate for lot i

$R_i$  = ratio of  $Y_i$  to  $Y_{i-1}$  ( $R_1 = 1$  since there is no previous lot)

$Xl_i$  = cumulative quantity through lot i-1

$Xu_i$  = cumulative quantity through lot i

A = constant

b = learning curve parameter

c = production rate parameter

d = rate change parameter

This formulation reverts back to the TASC form for periods of stable production rates. That is, if  $Y_i = Y_{i-1}$  then the value of  $R_i$  is one. This model follows the same logic as the TASC formulation and is therefore subject to the same criticisms.

Alternative one was analyzed by comparing the sum of squared residuals it yielded with those of the TASC model. The SAS output summary for alternative one is in Appendix D, section 4. Because the alternative formulation has four parameters, A, b, c, and d, it failed to provide predictions for those programs with four or less observations. This left 37 programs for which it was able to provide meaningful results. These results are listed below:

- All thirty-seven programs provided some improvement in residual sums of squares over the TASC formulation. The average improvement for these thirty-seven programs was 31.3% with a standard deviation of 27.4.
- Twenty-nine programs provided a ten percent or better improvement over the TASC model. The average improvement for these twenty-nine programs was 39.3% with a standard deviation of 25.6.

From this it is concluded that alternative one provides a significant improvement over the TASC formulation.

Analysis of 95% confidence intervals revealed results similar to those of the TASC model. Few programs showed that all four parameters were significant at this level. Even at the 80% level of confidence, no more than six programs could maintain statistical significance in all four parameters. None of the four parameters individually, A, b, c, or d, were consistently significant at either confidence level.

Alternative Two. The second alternative was introduced in equation 12. Integration with respect to X provides the following form:

$$TC_i' = \int_{Xl_i}^{Xu_i} AX^{(b+cY_i+dY_i^2)} dx =$$

$$A/(b+cY_i+dY_i^2+1)[Xu_i^{(b+cY_i+dY_i^2+1)} - Xl_i^{(b+cY_i+dY_i^2+1)}] \quad (14)$$

where

$TC_i'$  = estimated total cost of lot i

$Y_i$  = production rate for lot i (constant for a given lot)

$Xl_i$  = cumulative quantity through lot i-1

$Xu_i$  = cumulative quantity through lot i

A, b, c, d = model parameters

This formulation reverts back to the standard unit learning curve formulation if parameters c and d prove insignificant. Like alternative one this formulation failed to provide predictions for programs with four or less observations. The results of the 37 remaining programs are listed below:

- All but seven programs provided improvement in residual sums of squares over the TASC model. The average improvement for all programs was 27.9% with a standard deviation of 48.7.
- The average improvement for only those programs which improved was 47.5% with a standard deviation of 27.8.
- Nineteen programs showed significant improvements over alternative one.

From the information above it can be concluded that alternative two provides a significant improvement over the TASC formulation.

Analysis of 95% confidence revealed results similar to the previous two formulations. Few programs showed all parameters to be significant at the 95% level and made only minor improvement at the 80% level. None of the four parameters individually, A, b, c, or d, were consistently significant at either confidence level.

#### Comparison of Alternatives

Based on the results presented in the previous sections it can be concluded that both alternative one and alternative two provide more accurate estimates than the TASC formulation. Table II provides a summary of the residual sums of squares for all three formulations.

Since alternative one improved the residual sum of squares for every program while alternative two actually showed a decrease the residual sum of squares for seven programs it can be concluded that alternative one is more consistent than alternative two.

Although alternative two was better than alternative one for nineteen programs this left eighteen programs for which alternative one was

better. There is a pattern indicated by program type for distinguishing between alternatives one and two. Alternative one was consistently more accurate than alternative two for fighter aircraft, helicopters, and tactical missiles. Alternative two in turn was consistently more accurate for bomber aircraft, electronics, and tactical armaments.

## VI. Summary and Conclusion

The need to make decisions concerning production rate changes in today's cost conscious environment requires that accurate estimates be made of their impact on cost. The Analytic Sciences Corporation (TASC) developed a model for Air Force Systems Command (AFSC) for this purpose. This model, along with two alternative formulations of the production rate problem, was the subject of this investigation.

### Findings

Analysis of the current Systems Command (TASC) model indicates that, based on residual sum of squares, it is able to provide a significant improvement over the standard learning curve model which it is derived from. Several issues were raised with the TASC formulation and with TASC's analysis of it. First, the nonlinear curve fitting technique used by TASC requires that production rate be held constant for a given lot. It was concluded that this assumption would not significantly affect the results of the model for its intended purpose. Next, it was concluded that the failure of TASC's formulation to solve for the optimal rate of production which is indicated by the bathtub shaped long run cost curve will result in distorted parameter estimates if the data is not adjusted prior to curve fitting. Third, it was concluded that use of the pseudo- $R^2$  as a measure of fit is invalid and, finally, it was shown that the model parameters were not statistically significant on a consistent basis.

The first alternative production rate formulation, one which incorporates an additional variable for changes in production rate, showed that based on residual sum of squares it is capable of consistently

providing more accurate estimates than the TASC formulation. Since this first alternative is merely an extension of the TASC formulation it is subject to the same criticisms. Analysis also revealed that the parameters for alternative one were not consistently significant.

The second alternative is based on the unit learning curve model as are the TASC formulation and alternative one. However, this model incorporates an exponent which is a quadratic function of production rate. This allows it to be able to directly solve for an optimal production rate from the data. It was shown that based on residual sum of squares this model was also capable of providing more accurate estimates than the TASC formulation. However, like the other two models, none of the parameters for alternative two proved to be statistically significant on a consistent basis.

Comparison of the alternatives revealed that alternative one could provide more accurate estimates than the TASC formulation on a more consistent basis than alternative two. There is some evidence to suggest that alternative two will provide more accurate estimates than alternative one for certain types of programs however, this requires further research.

Based upon the above conclusions it is recommended that Systems Command immediately incorporate alternative one as the new AFSC production rate model. The conversion would only require the addition of the new production rate change variable to the current AFSC model. Additionally, since the new variable is based on production rate the resultant model would not require additional data which is not used in the current model. Parameters to update the Systems Command model database have already been estimated as part of this thesis and are included in

#### Appendix D, section 4.

##### Research Limitations

The research which is the subject of this thesis is subject to several limitations. The most obvious limitation is that of the three production rate formulations none have parameters which are statistically significant on a consistent basis. This could be caused by the small number of observations available for each program. Since all of the models are logically sound, it is assumed that if additional observations were available the statistical significance of the parameters would increase.

Another limitation is the fact that it was not possible to determine with certainty if the SAS nonlinear curve fitting procedure was capable of accurately replicating the results achieved using the TASC Rate Analysis Curve (TRAC) procedure. This limitation, which was discussed in chapter five, is due to unresolved issues with the output reported by TASC.

Finally, this research is limited in that the effects of production rate changes still cannot be separated from the effects of learning because of collinearity in the data (see chapter two). The nonlinear curve fitting techniques, although they avoid dealing with the problems of multicollinearity in the data, do not solve it. However, as long as the relationship among the model's variables remains constant this presents no particular problem for estimating.

##### Areas for Future Research

The issues involved with estimating the cost impact of production rate changes are far from resolved. Each new research effort brings an

answer a little closer while simultaneously raising still more issues. Thus, the subject is wide open to future investigation. Several topics are of particular interest.

As mentioned previously, alternatives one and two should be further investigated to determine if there is a relationship between program type and their relative abilities to provide more accurate estimates. If this could be adequately demonstrated it would suggest using both formulations according to their relative strengths.

Another area for future research is the idea of a "toe up" at the end of learning curves. Many programs experience a slight upturn in the learning curve during the last one or two production lots. This can be attributed in part to, among other things, workers attempting to forestall layoffs or transfers to others programs. It is also possible that the low rates of production typically encountered at the ends of major programs could be causing a flattening or even an upturn in the normal learning curve. If this could be empirically verified it would help further improve the accuracy of learning curve estimates.

Finally, a topic which is still wide open to research is the area of accounting for fixed overhead costs. Although it was decided that the affects of fixed costs could be ignored by considering only recurring costs, this is not entirely true. Since major defense contractors usually have the bulk of their business base tied up into just a few major contracts, large changes in the production rate of one program could have a significant cost impact on others due to the fact that fixed costs will be allocated over a smaller base. While this is not a production rate problem directly, the implications for decision makers trying to control weapon systems costs are the same.

## Appendix A: Data

All data used in this thesis was extracted from documentation of the Air Force Systems Command Production Rate Model which was developed by The Analytic Sciences Corporation (18). There are two key reasons for selecting this database. First, it was readily available in published documentation of the AFSC model. TASC originally obtained the raw data from official Air Force sources such as system program offices, the AFSC history office, and the Pentagon. The majority of this raw data was compiled during the AFSC sponsored Affordable Acquisition Approach study, completed in 1983 (15). The data was converted to constant 1984 dollars using rates supplied through the AFSC comptroller. Second, it was chosen to be consistent with the work TASC performed. This helps maintain the validity of the evaluation of the TASC model and provides a consistent basis for comparing the TASC model with other formulations.

The actual database consists of 35 programs in six categories including bomber aircraft, fighter aircraft, electronics, helicopters, tactical armaments, and tactical missiles. Some programs, such as the F-15 and F-16, were produced as different models (e.g. F-15A/B and F-15C/D). Others, such as the AIM-7F, were produced by multiple manufacturers (i.e. General Dynamics and Raytheon). Since differences among model types and manufacturers can influence learning and production rate considerations several programs have been broken out and their various excursions treated separately. This is consistent with TASC's work. Including the excursions there are a total of 41 separate data sets. Each set has from four to twelve observations with an average of seven.

All data in this appendix appears in millions of constant fiscal year 1984 dollars. Only recurring, average unit costs are given. Quantity values are for annual lots unless otherwise indicated (i.e. when multiple lots are given for a single fiscal year). Where necessary, values were converted to an annual production rate basis for consistency before analyses were performed. Units being produced concurrently for other services are included where applicable.

## Appendix B: Newton's Method

This appendix gives a brief description of the nonlinear curve fitting technique, Newton's Method, which forms the basis for TASC's approach to solving the current production rate formulation. This formulation can be found in chapter two, equation six.

To solve equation six for parameters A, b and, c TASC first solved for total lot cost ( $TC_i'$ ) as shown in chapter three, equation nine. Newton's Method then minimizes the sum of squared errors between this predicted total lot cost and the actual total lot cost as indicated in chapter three, equation ten. This equation is repeated below for convenience:

$$\sum_{i=1}^N w_i [TC_i - TC_i']^2 \quad (10)$$

where

$TC_i$  = actual total lot cost

$TC_i'$  = predicted total lot cost

N = total number of lots

$w_i$  = weight of lot i (where  $\sum w_i = 1$ )

To minimize the sum of squared errors between the actual and predicted total lot costs Newton's Method must be initialized with some arbitrary parameter values. (Note that a solution will be reached in less steps if the initial parameter values are close to the true parameters.) The sum of squared errors is calculated and then, based on a series of partial derivatives with respect to the parameters, Newton's Method calculates a new set of parameter values. The sum of squared

errors for this new set of parameters is then compared to the previous value. Successive iterations of this process eventually converge on a solution. The solution is reached when the decrease in sum of squared errors becomes infinitely small. (In practical applications an arbitrarily small value is used to evaluate convergence.)

This is a basic description of how Newton's Method is used to solve for the parameters in the three models in this thesis. For a more detailed, technical, discussion of Newton's Method refer to Linear and Nonlinear Programming, by David G. Luenberger (10).

## Appendix C: SAS Programs

This appendix lists the three Statistical Analysis System (SAS) programs used in this thesis. The first program includes a description of the program routines to assist future researchers. For a detailed discussion of the various program steps consult the SAS User's Guide: Statistics (11).

### C.1 - The TASC Formulation

This section presents the program which was used for the TASC formulation. It is based on the program provided to Air Force Systems Command by TASC in documentation of the AFSC production rate model (18: Appendix B, 6-7). The program has been modified somewhat so that the variable names are consistent with those used in this thesis.

```
CMS FILEDEF INP DISK BOMBER DATA;
```

This line identifies a datafile named BOMBER to the command system on the Boeing Computer Services system and gives it the name INP.

```
DATA INP;  
  INFILE INP;  
  INPUT SYS $ LOT QTY AUC;
```

These lines input data from the file INP. Four variables are input for each observation: (1) SYS \$ is the name of the weapon system, such as B-1B etc., (2) LOT is the production lot number, (3) QTY is the lot quantity and, (4) AUC is the average unit cost for the lot.

```
RETAIN XL 0 XU 0;  
  IF LOT = 1 THEN XU = 0;  
  IF LOT > 0 THEN XU + QTY;  
    XL = XU - QTY;  
  IF LOT = 1 THEN XL = .0000001;
```

These lines initialize the upper and lower bounds of each lot ( $X_u$ ,  $X_l$ ).

YI = QTY;

Sets production rate  $Y_1$  equal to lot quantity.

PLOTPT = XL + QTY/2;  
IF LOT = 1 THEN PLOTPT = 0.5 + QTY/3.0;

Sets rule of thumb lot plot points.

LLOTPT = LOG(PLOTPT);  
LAUC = LOG(AUC);  
LYI = LOG(YI);

Performs log-linear transformations.

TCA = QTY \* AUC;

Sets the actual total lot cost.

PROC SORT  
DATA = INP;  
BY SYS;

Sorts the data by system.

PROC REG  
OUTEST = EST;  
BY SYS;  
MODEL LAUC = LLOTPT LYI;  
DATA OUT;  
SET EST;  
A1 = EXP(INTERCEP);  
B1 = EXP(LLOTPT \* LOG(2));  
C1 = EXP(LYI \* LOG(2));  
DATA MER;  
MERGE INP OUT;  
BY SYS;  
DROP \_TYPE\_ \_MODEL\_ \_DEPVAR\_ \_SIGMA\_ LAUC;

Performs normal linear least squares regression on the transformed variables and creates the data set MER by merging the data set INP with the output from the regression procedure. The variables A1, B1 and, C1 will be used to initialize the search procedure in the PROC NLIN routine. This cuts down on the time needed for the nonlinear procedure to converge.

```

PROC NLIN
  DATA = MER
  METHOD = MARQUARDT
  MAXITER = 50
  CONVERGE = .0000000000000001;
  PARMS A = 1
        B = 1
        C = 1;
  IF _ITER_ = 0 THEN IF _N_ = 1 THEN DO;
    A = A1;
    B = LOG(B1)/LOG(2);
    C = LOG(C1)/LOG(2);
  END;

```

This routine initializes the PROC NLIN procedure.

```

MODEL TCA = YI**C * (XU**(B+1) - XL**(B+1)) * A / (B+1);
DER.A = YI**C * (XU**(B+1) - XL**(B+1)) / (B+1);
DER.B = A * YI**C * (XU**(B+1) * LOG(XU) - XL**(B+1) * LOG(XL))
        / (B+1) - YI**C * (XU**(B+1) - XL**(B+1)) * A / (B+1)**2;
DER.C = LOG(YI) * (XU**(B+1) - XL**(B+1)) * YI**C * A / (B+1);

```

These five lines give the model and derivative statements needed to run PROC NLIN.

```

  BY SYS;
  OUTPUT OUT = NOUT
        PARMS = AO BO CO
        PREDICTED = TCP
        SSE = SS
        RESIDUAL = RES;
  DATA OUT2;
  SET NOUT;
  SB = EXP(BO * LOG(2));
  SC = EXP(CO * LOG(2));
  UCP = TCP/QTY;
  DIF = AUC - UCP;
  PCT = 100 * DIF/AUC;
PROC PRINT
  DATA = OUT2;
  VAR LOT XL XU YI AUC UCP DIF PCT SB SC;
  BY SYS;

```

These lines prepare the output from PROC NLIN into the report form used in Appendix D.

## C.2 - Alternative One

This section presents the program used for alternative one.

```

      CMS FILEDEF INP DISK BOMBER DATA;
DATA INP;
  INFILE INP;
  INPUT SYS $ LOT QTY AUC;
  RETAIN XL 0 XU 0 VI 0 YI 0;
  IF LOT = 1 THEN XU = 0;
  IF LOT > 0 THEN XU + QTY;
  XL = XU - QTY;
  IF LOT = 1 THEN XL = .0000001;
  YI = QTY;
  PLOTPT = XL + QTY/2;
  IF LOT = 1 THEN PLOTPT = 0.5 + QTY/3.0;
  L PLOTPT = LOG(PLOTPT);
  LAUC = LOG(AUC);
  TCA = QTY * AUC;
  LYI = LOG(YI);
  IF LOT = 1 THEN VI = 1;
  IF LOT > 1 THEN VI = QTY/LAG1(QTY);
PROC SORT DATA = INP;
  BY SYS;
PROC REG NOPRINT OUTEST = EST;
  BY SYS;
  MODEL LAUC = L PLOTPT LYI;
  DATA OUT;
  SET EST;
  A1 = EXP(INTERCEP);
  B1 = EXP(L PLOTPT * LOG(2));
  C1 = EXP(LYI * LOG(2));

  MERGE INP OUT;
  BY SYS;
  DROP TYPE MODEL _DEPVAR _SIGMA LAUC;
PROC NLIN DATA = MER
  METHOD = MARQUARDT
  MAXITER = 100
  CONVERGE = .00000000000000001;
  PARMS A = 1
         B = 1
         C = 1
         D = 1;
  IF _ITER_ = 0 THEN IF _N_ = 1 THEN DO;
    A = A1;
    B = LOG(B1)/LOG(2);
    C = LOG(C1)/LOG(2);
    D = .1;
  END;
  MODEL TCA = YI**C * VI**D * (XU**(B+1) - XL**(B+1)) * A / (B+1);
  DER.A = YI**C * VI**D * (XU**(B+1) - XL**(B+1)) / (B+1);
  DER.B = (XU**(B+1)*LOG(XU)-XL**(B+1)*LOG(XL))*A*YI**C*VI**D/
    (B+1) - YI**C*VI**D*(XU**(B+1)-XL**(B+1))*A/(B+1)**2;
  DER.C = LOG(YI)*(XU**(B+1)-XL**(B+1))*YI**C*VI**D*A/(B+1);
  DER.D = LOG(VI)*(XU**(B+1)-XL**(B+1))*YI**C*VI**D*A/(B+1);
  BY SYS;

```

```

OUTPUT OUT = NOUT PARMS = AO BO CO DO PREDICTED = TCP SSE = SS
      RESIDUAL = RES;
DATA OUT2;
SET NOUT;
  SB = EXP(BO * LOG(2));
  SC = EXP(CO * LOG(2));
  UCP = TCP/QTY;
  DIF = AUC - UCP;
  PCT = 100 * DIF/AUC;
PROC PRINT DATA = OUT2;
  VAR LOT XL XU YI VI AUC UCP DIF PCT;
  BY SYS;

```

### C.3 - Alternative Two

This section presents the program used for alternative two.

```

CMS FILEDEF INP DISK TMISS DATA;
DATA INP;
  INFILE INP;
  INPUT SYS $ LOT QTY AUC;
  RETAIN XL 0 XU 0;
  IF LOT = 1 THEN XU = 0;
  IF LOT > 0 THEN XU + QTY;
  XL = XU - QTY;

```

## Appendix D: Computer Output Summary

This appendix contains summary results of the various computer runs used for the analyses in this thesis. Results are categorized by computer run and subcategorized by program type and then by program.

### D.1 - ICLOT Runs

This first set of results is from the ICLOT learning curve program. Access to the ICLOT program was through the Boeing Computer Services system. Values for the sum of squared residuals were not output by ICLOT. These were calculated by hand and are based on actual and predicted total lot costs to be consistent with the SAS output.

## D.2 - TASC Formulation, SAS Runs

This section contains summary results produced using the Statistical Analysis System (SAS) nonlinear curve fitting procedure PROC NLIN on the TASC formulation. The program used to generate these results was discussed in Appendix C. Access to SAS was gained through the Boeing Computer Services system.

## VITA

Captain Hugh K. Bolton was born on 5 February 1959 in Browns Mills, New Jersey. He graduated from Pemberton Township High School in Pemberton, New Jersey, in 1977 and attended the United States Air Force Academy from which he received the degree of Bachelor of Science in May 1981. Upon graduation he was assigned to Headquarters Air Force Systems Command at Andrews Air Force Base, Washington DC. He served there as a cost analysis officer in the Directorate of Cost and Management Analysis, Deputy Chief of Staff Comptroller, until entering the School of Systems and Logistics, Air Force Institute of Technology, in June 1984.

The need to make decisions concerning production rate changes in today's cost conscious environment requires that accurate estimates be made of their impact on cost. The Analytic Sciences Corporation (TASC) developed a model for Air Force Systems Command (AFSC) for this purpose. This model, along with two alternative formulations of the production rate problem is the subject of this investigation.

Based on this analysis it has been determined that the current AFSC model is capable of providing more accurate estimates than the standard unit learning curve model which it is derived from. The first alternative formulation, which includes an additional variable to account for changes in production rate, was shown to consistently provide more accurate estimates than the current model. Since it is based on the current formulation, it can easily be incorporated into the present AFSC model. It is recommended that Systems Command do so. The second formulation, which is based on the unit learning curve model with the exponent expressed as a function of production rate, also provides more accurate estimates than the current formulation though, not as consistently. There is evidence which suggests that this formulation is capable of providing more accurate estimates than the first alternative for certain types of programs. It is recommended that this be further investigated. (THC/S)
